ABSTRACT

Turbulent mixing* rates between two adjacent rectangular channels (0.80 in. x .74 in.) were measured for single phase air, single phase water, and two-phase air-water flows. Methane was employed as the air tracer and potassium nitrate (KNO_3) as the water tracer. A gas chromatograph and an atomic absorption unit were used for gas and liquid analyses respectively.

Single phase air turbulent mixing rates were determined at a system pressure of 50 psia using interconnection gaps 100 mils wide and 2,4,6,10,14 inches long. Also a 40 mil gap and 4 inch long interconnection path was used. The Reynold's number ranged from 15,000 - 150,000. In all cases the subchannel dividing strip was 0.125 inches thick.

Data for single phase water were taken at atmospheric pressure employing a gap of 100 mils and 4,10, and 14 inch long interconnection lengths. Reynold's numbers for single phase water flows were varied from 5000 to 30,000. The turbulent mixing data exhibited entrance effects similar to those previously observed in heat transfer under analogous conditions.

* Turbulent mixing is defined here as transfer of fluid between adjacent subchannels due to the random motion of turbulent flow.

Two-phase two-component turbulent mixing was studied for an air-water system with a gap of 100 mils and an interconnection-length 10 inches long. All data points were taken at a pressure of 50 psia. Quality was varied from 20% to 80% at four different mass fluxes. The percentages of air and water in a subchannel which mixed increased significantly as the quality* and mass flux decreased. It is postulated that the transitional flow regime from slug to annular flow and the presence of large roll waves give rise to this phenomena.

* Quality is defined here as the ratio of air mass flow rate to the total air and water mass flow rates.

AKNOWLEDGEMENTS

The author wishes to express his gratitude to Dr. C. St. Pierre for his assistance and advice in this study.

The experimental work for this thesis was performed at the Chalk River Nuclear Laboratories. Thanks are due to Mr. G.A. Wikhammer, Mr. S. Harris, Dr. D. McPherson, Dr. N. Sagert and Mr. A. Smith for their advice and assistance. Thanks are also due to Mr. O. Brudy, Mr. P. Liebsch and Mr. W. Wilke who constructed the test section used in this study.

The financial support provided by the National Research Council and Atomic Energy of Canada Limited is gratefully acknowledged.

I INTRODUCTION

The object of the present work was to measure the turbulent mixing rate between two adjacent interconnected rectangular subchannels* in which single phase air, single phase water, and two-phase air-water mixtures are flowing.

In the early design of heat exchange systems for Canadian nuclear reactors, experiments were performed on multi-rod bundles to determine the kinds and amount of interaction between interconnected subchannels. When one subchannel has a higher power factor than those adjoining, this can lead to critical heat flux conditions prematurely in this subchannel. However energy transfer by turbulent mixing from the hot channel to the colder channels gives rise to improved performance. Hence an accurate prediction of turbulent mixing will allow power reactors to be designed to operate at maximum thermal efficiency and economy.

There are two main classifications of interactions between adjacent subchannels. The first is generally given the name crossflow or diversion flow. Crossflow is defined as the net transfer of fluid from one subchannel to another when radial pressure gradients are the driving force. The second interaction phenomena is termed turbulent mixing. Turbulent mixing is the interchange of fluid between adjacent

* Subchannel is defined here as the flow area formed by drawing a line between the rod centres of a rod (tube) bundle heat exchanger. See Fig. 1.1.

Total Number of Subchannels = 20

Total Number of Distinct Subchannels = 5

FIG. 1.1 Typical Rod Bundle Cross Section

subchannels due to the fluid flow turbulence. In this second type of interaction there is no net transfer of fluid between subchannels.

The effect of interconnection length and gap width on the degree of turbulent mixing for single phase air and single phase water were studied. In addition two-phase air-water mixing rates were measured as

a function of quality and mass flux.

In order to ensure that turbulent mixing measurements were not influenced by crossflow two conditions were maintained. First, equal pressure drops in each subchannel were obtained by use of upstream and downstream drag adjustments (when required). Secondly for each data point, mixing rates were measured for tracer being injected first into the left and then the right subchannel. If the values for left and right subchannel tracer injection differed by more than $\pm 10\%$ indicating significant crossflow, then they were rejected and the run repeated.

The tracers used were methane for the gas phase and potassium nitrate for the water. Analyses of the methane air tracer were made on a gas chromatograph and the liquid phase tracer concentrations were determined by atomic absorption.

Since this was a basic study of turbulent mixing, the simplest subchannel array was chosen. See Fig. 1.2. It consisted of two rectangular channels formed by a $1/8$ inch dividing strip which had cut in it slits of various lengths and widths (gaps).

II LITERATURE SURVEY

A. Introduction

An excellent discussion of turbulent mixing and available correlations has been given by Rogers and Todreas [1]. Rogers and Todreas defined two new types of mixing: flow scattering and flow sweeping. Flow scattering is due to the presence of rod spacers and fuel bundle end plate assemblies which induce turbulence. This phenomena is said to be non directional. Flow sweeping has a directional flow effect caused by wire wrap spacers, helical fins, etc. This is essentially a crossflow phenomena since it results in a net transfer of fluid from one subchannel to another.

Turbulent mixing (without any turbulence promoters) results from the random motion of macroscopic portions of the fluid stream flowing under turbulent flow conditions. Heat and mass transfer data for systems in turbulent flow are often correlated using the concept of turbulent or eddy diffusivities for heat or mass. Because of the nature of turbulent flow there is an increase in the transport properties of the fluid and molecular diffusion becomes negligible compared to turbulent diffusion. The equations for heat and mass transfer can be written as follows:

Molecular

$$\text{heat} \quad Q = -(k/\rho C_p)(\nabla \rho C_p T) \quad (2.1)$$

$$\text{mass} \quad J_A = -D \nabla C \quad (2.2)$$

Turbulent

$$\text{heat} \quad Q = -(k/\rho C_p + E_H) \nabla \rho C_p T \approx -E_H \nabla \rho C_p T \quad (2.3)$$

$$\text{mass} \quad J_A = -(D + E_m) \nabla C \approx -E_m \nabla C \quad (2.4)$$

where

| | | |
|--------|---------------------------|------------------------------|
| C | = concentration | lbm/ft ³ |
| C_p | = heat capacity | BTU/lb °F |
| D | = molecular diffusivity | ft ² /hr |
| E_H | = eddy diffusivity (heat) | ft ² /hr |
| E_m | = eddy diffusivity (mass) | ft ² /hr |
| J_A | = mass flux of A | lb/hr ft ² |
| k | = thermal conductivity | BTU/hr ft ² °F/ft |
| Q | = heat flux | BTU/hr ft ² |
| T | = temperature | °F |
| ρ | = density | lb/ft ³ |

The eddy diffusivities for heat and mass have been found to be equal [1,2,3]. Mass diffusion studies have been used to predict turbulent heat transfer rates.

B. Single Channel Experiments

There are two basic approaches in the experimental determination of turbulent (eddy) diffusivities. The first involves the addition of tracers (or heat) into a fluid stream and subsequent concentration (or temperature) measurements downstream. Wilson[4] integrated the steady state Fourier heat conduction equation for the continuous addition of heat from a point source in an infinite fluid stream moving at a uniform velocity in one direction. Measurements of

axial or radial temperature (concentration) profiles used in conjunction with Wilson's solution enables the determination of the turbulent diffusivities for heat (mass) transfer. This approach was used by Towle and Sherwood [5], Slember [6], McCarter, Stutzman and Koch [7], and Pfennigworth and Steer [8].

An alternate approach is to measure eddy diffusivities by determining the rate of water transfer from a liquid film (viz. wetted wall column) as done by Sherwood and Woertz [9] and Dhanack [10].

Most of the available data has been correlated by St. Pierre^[11] and plotted as ψ versus N_{Re} , where ψ is the inverse of the Peclet number. This represents the ratio of turbulent conductive mass transfer to bulk mass transfer ($\psi = \frac{E}{\langle V \rangle De}$).

The major problem with this approach lies in the fact that the values of turbulent diffusivities obtained are for the case of a single channel. For subchannel analysis they must be applied to the region between subchannels and for different rod cluster geometries. An order of magnitude value for turbulent mixing between subchannels can be determined employing eddy diffusivities from the above methods but it is not sufficiently accurate to meet present requirements for a rigorous subchannel analysis.

C. Multi-Channel (Rod Bundle) Experiments

Tracer experiments have been carried out in multirod bundles to determine flow interchange between subchannels. It is important to note that in this type of analysis some crossflow effects may also be present. The total flow redistribution from all effects is measured.

A tracer (hot water, salt, dye, gas) is injected in one subchannel and concentrations measured in adjacent channels downstream to determine the rate of flow interchange. A tracer mass balance is used to calculate a mixing coefficient.

Rogers [12] has employed rod bundle mixing data and proposed a correlation for single phase fluid interchange for rod bundles. Taking an energy balance between the heat transport rate by the postulated mixing flow and the radial heat transport by eddy diffusivity between any two channels i and j he develops a relationship for flow mixing between adjacent subchannels:

$$\omega^t C_p (\bar{T}_i - \bar{T}_j) = \rho C_p b L E_{ij} \left(\frac{dT}{dr} \right) \quad (2.5)$$

By writing the mean temperature gradient as $(\bar{T}_i - \bar{T}_j)/Z_{ij}$ where Z_{ij} is an intersubchannel distance equation (2.5) can be rewritten as:

$$\frac{\omega^t}{L} = \frac{\rho b E_{ij}}{Z_{ij}} \quad (2.6)$$

This form of equation is analogous to those proposed by St. Pierre [11], Bowring [13] and Rowe and Angle [14].

St. Pierre

$$\frac{\omega^t}{L} = \frac{\rho b E}{1/2 (R_{eqi} + R_{eqj})} \quad (2.7)$$

Bowring

$$\frac{\omega^t}{L} = \frac{F_m}{S_m} \frac{b}{d} E \rho \quad (2.8)$$

Rowe and Angle

$$\omega^t = \frac{\rho b E}{\Delta y} \quad (2.9)$$

where

| | | |
|------------|---|---------------------|
| ω^t | = mixing rate | lb/hr |
| ρ | = density | lb/ft ³ |
| b | = gap width | ft |
| d | = rod diameter | ft |
| R_{eq} | = 1/2 equivalent diameter | ft |
| E | = eddy diffusivity | ft ² /hr |
| Δy | = gap width (in correlation) | ft |
| S_m | = gap shape factor | - |
| F_m | = empirical mixing factor to account for turbulence promoters | - |

It is evident that the above equations are identical in form differing only in the definition of an intersubchannel distance.

Rogers [12] postulates that Z_{ij} is a function of (b/d) and using the data of Clarke [15], Tarasuk and Kempe [16], Collins and France [17], Bishop [18], Nelson [19], Dean [20], Biggs and Rust [21] has developed an empirical correlation which predicts mixing as a function of (b/d) . Rogers correlation predicts a constant mixing rate for $.05 < b/d < .5$ since both Z_{ij} and E_{ij} decrease at the same rate as (b/d) decrease. For $b/d < .05$ there was an increase in mixing rate with decreasing b/d . This correlation would suggest that single channel diffusivities cannot be applied to rod bundles since E is a function of b/d . The next approach followed in mixing experiments between adjacent subchannels is that in which both subchannels are pressure balanced to eliminate radial pressure gradients and hence crossflow.

D. Two Channel Experiments

1. Singleton [22]

Limited data have been obtained for single phase turbulent mixing between similar adjacent subchannels. Singleton measured water mixing rates between adjacent subchannels using a dye as a tracer. His subchannel arrangements are detailed in Fig. 2.1. For the square fillers at the same Reynold's number the mixing rate increase was approximately 1.4 times that given by the ratio of the gap widths. For the round fillers at the same Reynold's number the mixing rate increase was approximately proportional to the ratio of the gap widths. Mixing is increasing with gap width but the mixing for the square filler increased more than the gap width ratio. The cause is not readily explainable. Singleton evaluated his data in terms of a mixing coefficient and his data were reanalyzed in terms of an equivalent Stanton number for purpose of comparison here. (See Appendix III).

2. Rowe and Angle [23,24]

Rowe and Angle have obtained turbulent mixing data between adjacent triangular-rectangular subchannels by measuring the enthalpy rise in a heated test section. Their equation for mixing was obtained by using their computer code [14] to determine a Stanton number which most closely matched their experimental results. Three data points were obtained for $(b/d) = 0.0355$ and eight data points for $(b/d) = 0.149$. Their correlation predicts the mixing rate to be independent of rod spacing.

Data were taken also for a square-square subchannel array (Fig. 2.1) using lithium hydroxide as a tracer. Here their computer

FIG. 2.1

Subchannel Details of Singleton and Rowe and Angle

code yielded a correlation which predicted that the mixing rate was again independent of (b/d) .

Mixing for the square square array was less than for the square triangular array. Hence mixing decreased as the centroidal distance between two subchannels increased.

Further experimental data are necessary for single phase mixing as there is presently insufficient data to predict turbulent mixing rates for all types of subchannels and all ratios of gap width to rod diameter.

E. Single Phase Turbulent Mixing Correlations

1. St. Pierre Correlation [11]

St. Pierre has proposed a correlation for turbulent mixing rates based on values of turbulent diffusivities obtained from single channel experiments.

$$\frac{\omega^t}{L} = \frac{b \rho E}{1/2 (R_{eqi} + R_{eqj})} = 2bG\psi \quad (2.10)$$

where

$$\psi = .0205 N_{Re}^{0.0205} \quad N_{Re} > 5000.$$

2. Bowring Correlation [13]

Bowring has developed a subchannel code Hambo in which the following single phase mixing equation is used.

$$\begin{aligned} \frac{\omega^t}{L} &= \frac{F_m}{S_m} \frac{b}{d} E \rho \\ &= \frac{F_m}{d} \frac{b}{S_m} \frac{f_i + f_j}{80} (D_i G_i + D_j G_j) \end{aligned} \quad (2.11)$$

Assuming equal subchannels and $F_m = 1$.

$$\frac{\omega^t}{L} = \frac{b}{d S_m} (.215 N_{Re}^{-.1}) DG. \quad (2.12)$$

3. Rogers and Tarasuk Correlation [12]

Using the experimental data outlined previously Rogers and Tarasuk have developed a correlation from multi-channel experiments.

$$N_{st} = \frac{k}{2} (b/d)^{-r} N_{Re}^{m-1} \left(1 + \frac{De_i}{De_i} \frac{3m}{2-n}\right) \frac{De}{d} \quad (2.13)$$

Values of m, n, k , and r were obtained from an analysis of the experimental data. Considering two similar adjacent subchannels the above expression reduced to:

$$N_{st} = \frac{.0503}{2} (b/d)^{-1.57} N_{Re}^{-.32} (1+1) \frac{De}{d} \quad (2.14)$$

or Roger's correlation No. 1:

$$\frac{\omega^t}{L} = .0503 (d/b)^{.57} De G N_{Re}^{-.32} \quad (2.15)$$

Rogers [25] has modified the above correlation to account for the difference in subchannel arrays. A tentative equation (Roger's correlation No.2) has been proposed as:

$$\frac{\omega^t}{L} = .050 De G N_{Re}^{-.32} \quad (2.16)$$

Additional data and reanalysis [25] have shown that the correlation for similar subchannels reduces to a form identical with that of Rowe and Angles correlation. The only difference lies in the constant being 0.0035 for Roger's and 0.0036 for Rowe and Angle. In this reanalysis Rogers shows that mixing rates from rod bundle experiments are approximately 2.3 times that of subchannel experiments.

4. Rowe and Angle Correlation [23,24]

The Rowe and Angle correlation was developed by finding a value of the equivalent Stanton number which most closely matched their experimental data.

$$N_{st} = Kr \left(\frac{De}{Z_{ij}} \right) N_{Re}^{-n/2} \quad (2.17)$$

where

$$Kr = .0062 \quad \text{triangular-square array}$$

$$Kr = .0036 \quad \text{square-square array}$$

$$n = .2$$

$$Z_{ij} = b(\text{gap width})$$

With the above values for the constant Eq. (2.17) reduces to:

$$\frac{\omega^t}{L} = Kr \frac{De}{b} G N_{Re}^{-.1} \quad (2.18)$$

5. Moyer Correlation [26]

Moyer has proposed the following correlation for turbulent mixing:

$$\frac{\omega^t}{L} = \frac{(2a)^{1/2}}{40} \frac{De}{Z_{ij}} b G N_{Re}^{-n/2} \quad (2.19)$$

where:

$$n = .2$$

$$a = .0405 \quad \text{i.e. } f = a N_{Re}^{-n}$$

$$Z_{ij} = \text{centroidal distance between subchannels}$$

$$\frac{\omega^t}{L} = .0255 \frac{De}{Z_{ij}} b G N_{Re}^{-.1} \quad (2.20)$$

F. Two Phase Turbulent Mixing Data

Experimental data for two phase turbulent mixing are very limited. Bestenbreuer and Spight [27] have injected air in one subchannel and measured the mass flow of air and water at the outlet of the channels.

Rowe and Angle [23,24] have obtained experimental data on two phase steam water turbulent mixing at elevated pressures. The first experiments were carried out using a triangular-rectangular subchannel array. Their data were analyzed and a mixing coefficient β (which is equivalent to N_{st}) obtained from an enthalpy balance on their heated test section using their computer code. The results are summarized below in Table 2.1.

TABLE 2.1

Two-Phase Mixing Data of Rowe and Angle Triangular-Square Array

| b | 6×10^{-6} | β | β | Boiling Mixing |
|--------|-----------------------|-------------|---------|----------------|
| inches | lb/hr ft ² | non-boiling | boiling | Increase % |
| .084 | 1 | .006 | .024 | 300 |
| .084 | 2 | .006 | .012 | 100 |
| .084 | 3 | .006 | .012 | 100 |
| .020 | 2 | .020 | .020 | 0 |
| .020 | 3 | .020 | .020 | 0 |

Further experiments were carried out with a square-square subchannel array using lithium hydroxide as the liquid tracer and deuterium and tritium as total tracers since the proportion of the latter two is about equal for liquid and vapour. Their results showed that a maximum value of mixing was reached at low qualities and that the percent mixing

increased with increasing mass flux. The ratio of steam to water mixing was found to be equal to the ratio of the total steam flow to the total water flow.

III THEORY

A. Derivation of Mixing Equation

Consider a fluid passing under turbulent flow conditions through two identical parallel channels interconnected through a gap parallel to the flow direction. Since turbulent flow is characterized by random fluctuations in the fluid velocity, movement of macroscopic portions of the fluid stream gives rise to a phenomena known as turbulent mixing. Turbulent mixing does not result in a net transfer of fluid between interconnected subchannels. Small masses of fluid move from one channel to the other but the total flow in each channel remains the same.

In order to determine the amount of mixing taking place, a tracer is injected into one subchannel and an equal mass of fluid in the other subchannel so that the subchannel flows remain equal. Measurements of the tracer concentrations in each subchannel can then be used to determine the degree of turbulent mixing.

Basic Assumptions:

(1) The total flow of fluid plus tracer is identical in each subchannel.

(2) The geometry of each subchannel is identical.

Hence the axial pressure gradients are identical and no radial pressure gradients exist.

(3) The tracer concentration is small and has no effect on the flow properties of the carrier fluid.

(4) Fluid moving from one subchannel to the other is assumed to have the average properties (concentration of tracer) of the channel which it is leaving. Also, when a small mass of fluid enters a subchannel it mixes quickly with the fluid in that channel.

Consider a tracer mass balance on subchannel 1 in the following figure.

Fig. 3.1 Mixing Flow Diagram

$$\omega_1 C_1 + \omega^t \left(\frac{C_2' + C_2}{2} \right) - \omega^t \left(\frac{C_1' + C_1}{2} \right) = \omega_1' C_1' \quad (3.1)$$

Assume that the tracer is injected in channel 1. Therefore $C_2 = 0$ and noting that $\omega_1 = \omega_2 = \omega_1' = \omega_2'$:

$$\omega(C_1 - C_1') = \frac{\omega^t}{2} (C_1' + C_1 - C_2') \quad (3.2)$$

From an overall tracer balance:

$$C_1 = C_1' + C_2' \quad (3.3)$$

Substituting Eq. (3.3) in (3.2)

$$\omega C_2' = \frac{\omega^t}{2} (C_1' + C_1' + C_2' - C_2') \quad (3.4)$$

which reduces to:

$$\omega^t = \omega \left(\frac{C_2'}{C_1'} \right) \quad (3.5)$$

As long as $C_1 \approx C_1'$ employing the arithmetic mean for sub-channel concentrations should be valid.

Mixing can also be determined using a differential tracer balance on subchannel 1. Expressing the concentrations as relative concentrations i.e. $C_1^* + C_2^* = 1$ the differential tracer balance can be written as

$$\omega_2 C_2^* + \omega^t C_1^* dx - \omega^t C_2^* dx = \omega_2 C_2^* - \omega dC_2^* \quad (3.6)$$

This reduces to

$$\frac{dC_2^*}{dx} = \frac{\omega^t (C_1^* - C_2^*)}{\omega} \quad (3.7)$$

Since $C_1^* + C_2^* = 1$ Eq. (3.7) becomes

$$\frac{dC_2^*}{dx} = \frac{\omega^t}{\omega} (1 - 2 C_1^*) \quad (3.8)$$

This can be solved to give

$$\frac{C_2'}{C_1} = 1/2 [1 - \exp(-\frac{2\omega^t L}{\omega})] \quad (3.9)$$

There was no difference between the calculated values of ω^t employing Eq. (3.5) and Eq. (3.9) in this analysis.

B. Discussion of Flow Regimes

Two phase mixing is expected to be a strong function of flow regime. Basically there are four main two-phase flow patterns along with transition regions between them. These are bubble flow, slug flow, annular flow and mist flow (Fig. 3.2). In bubble flow the liquid is the continuous phase with the vapour bubbles as the discontinuous phase. As the number of bubbles increases (increasing quality) they coalesce to form long slug like bubbles. As the quality increases further the slugs break down to form an annular flow. This is characterized by a film of liquid on the channel wall and entrained liquid in the core of the channel. Finally increasing the quality still further, more of the liquid is stripped from the wall and entrained in the core. This is known as fog or mist flow. The prediction of the transition between regimes is important in order to predict two-phase turbulent mixing rates.

A correlation for predicting the transition regime from slug to annular is given by Wallis [28]. Criteria for annular flow are presented in terms of j_g^* and j_l^* which are dimensionless gas and liquid velocities. The data are plotted in Fig. (3.3). All the data taken here lie in the annular flow regime or fog flow regime.

IV AIR-WATER TEST LOOP AND ASSOCIATED EQUIPMENT

A. Experimental Equipment

1. Air-Water Test Loop

The air-water test loop WAFER* and associated equipment used in this study were located in the Advance Engineering Building at Chalk River Nuclear Laboratories. Initially this loop was designed and constructed [29] to permit two-phase flow studies on prototype nuclear reactor rod bundle geometries. For the purposes of this mixing experiment minor modifications were made to the loop.

The air-water test loop used in this study consisted essentially of a regulated 100 psig air supply, a centrifugal pump for water circulation, an orifice metering system, a test section assembly, and a cyclone separator.

The loop is diagrammed schematically in Fig. 4.1.

Air from a 100 psig. air service line of the plant was filtered and metered through a bank of four orifices to the mixer. An air vent valve on the separator was employed to maintain a constant test section pressure at the beginning of the interconnection length for all experimental runs.

Water was supplied by a Durco (Model H7RDR4) centrifugal pump which could provide 100 IGPM at a head of 107 psia.

*

Water Air Fog Experimental Rig located at Chalk River Nuclear Laboratories (Building 456).

FIG. 4.1 Schematic Flow Diagram of WAFER

A bank of four orifice meters was employed to meter the water flows before entering the mixer. In addition a flowmeter with 1200 lbm/hr capacity was placed in parallel with the four water orifices to measure the low water flow rates.

After the test section assembly, a cyclone separator with a capacity of 6000 lbm/hr of air and 30,000 lbm/hr of water was used to separate the water from the air. The air leaving the separator passed through a pressure control valve and then was vented to the atmosphere. The water passed through a 2-inch ball float trap to a downcomer. It then could be sent to a drain or recycled to a 200 IG. feed storage tank. In order to avoid tracer contamination the loop was operated on a once-through basis.

2. Test Section Assembly

The test section assembly consisted of six sections:

I - air-water mixer, II - entrance section, III - separated subchannels, IV - interconnected subchannels, V - separated flow channels, VI - sampling section. A detailed drawing of the test section assembly is given in Fig. 4.2. The test section was fabricated entirely from acrylic to allow visual identification of the flow regimes. The various sections were butted together using 0.005 inch thick natural rubber gaskets cut to fit the channel shape.

(a) Mixer Section.

The air-water mixer consisted of an annular ring surrounding the rectangular channel at the test section entrance. Six 3/8 inch holes through which the water passed were drilled in the channel wall.

FIG. 4.2

TEST SECTION ASSEMBLY

217505

The air passed directly into the rectangular test section.

(b) Entrance Section.

The 22 inch entrance section was located after the mixer to allow the flow to develop before being split into two subchannels.

(c) Separated Subchannels.

The rectangular flow area was split here into two subchannels 36-13/22 long by means of a 1/8 inch dividing strip. The downstream edge of the dividing strip was in the form of a knife edge to reduce flow turbulence. Injection probes for the air and water tracers were located just after the flow was split. The probes are detailed in Fig. 4.2.

(d) Interconnected Subchannels.

Mixing occurred in this 16-7/16 inch section through the gap in the dividing strip. An O-ring seal was employed around the dividing strip to facilitate removal when changing the interconnection dimensions.

(e) Separated Channels.

The subchannel flows were separated here and entered seven foot long 0.812 inch stainless steel tubes. This was done to ensure adequate mixing of tracer.

(f) Sampling Section.

A portion of the total flow was taken from each of the stainless steel tubes and passed continuously to a small air-water separator. The bulk flow went to an air-water separator where the water removed was sent to the drain and air vented to atmosphere. The air exit line contained a back pressure valve which was used to control the

test section pressure. Air samples were collected in glass sampling tubes with stopcocks at each end. The water samples were collected in polyethylene bottles for later analysis.

B. Measurement of Loop Variables

1. Pressure Measurements

Three pressure rings were used to measure the radial pressure gradients which would cause crossflow. Each ring was constructed of two halves which were completely separated. Three static pressure taps were drilled from each half into the channel. See Fig. 4.2 for details.

The static pressure at the beginning of the subchannel interconnection length was maintained at 50 psia by means of a manual pressure control valve on the air outlet line of the separator. The axial pressure drop was measured employing the first two pressure rings. Radial pressure gradients were measured employing inclined manometers graduated to hundredths of an inch of water.

2. Flow Measurements

(a) Air

An automatic control loop maintained a constant test section flow. Four orifices were used as the primary flow measurement devices in conjunction with one differential pressure transmitter.

The orifices and assemblies conformed to ASME specifications [30] and were calibrated for the four following ranges detailed in Table 4.1.

TABLE 4.1
Air Orifice Specifications

| Fig. 4.1 Designation | Orifice Diameter (in.) | Range (lbm/hr) |
|----------------------|------------------------|----------------|
| FE - 2/1 | 1.941 | 1700 - 6000 |
| FE - 2/2 | 1.087 | 500 - 1800 |
| FE - 2/3 | 0.6455 | 160 - 600 |
| FE - 2/4 | 0.3540 | 40 - 180 |

(b) Water

Water flow rates to the test section were automatically controlled over the range 500 to 50,000 lbm/hr at loop operating pressures up to 100 psig. Four orifices meeting ASME specifications were also used in conjunction with one differential pressure transducer to meter the water flows to the test section. (See Table 4.2). All orifices were calibrated over this temperature range 45°F to 100°F.

TABLE 4.2
Water Orifices

| Fig. 4.1 Designation | Orifice Diameter (in.) | Range (lbm/hr) |
|----------------------|------------------------|-----------------|
| FE - 1/1 | 1.665 | 12,000 - 50,000 |
| FE - 1/2 | 0.9255 | 4,000 - 15,000 |
| FE - 1/3 | 0.5400 | 1,400 - 5,000 |
| FE - 1/4 | 0.2960 | 500 - 1500 |

3. Temperature

The temperature of both the air and water flow streams was measured using liquid filled thermocouple wells in the flow lines immediately after the orifice banks.

4. Tracer Concentrations

(a) Potassium Nitrate Analysis

Potassium nitrate (Anachemia purified) was used to make up the liquid tracer solution. Air pressure at 100 psig. over the potassium nitrate reservoir was used to force the tracer into the test section.

Potassium concentrations were measured using a Perkin Elmer 290 B atomic absorption analyzer with a hollow cathode potassium lamp. The atomic absorption analyzer was calibrated before each analysis over the working concentration range of zero to ten parts per million. Samples were diluted to fall into this range. Analyses were reproducible to $\pm 1.5\%$.

(b) Methane Analysis

The methane tracer was supplied from gas cylinders (Matheson technical grade). The air samples taken in the glass sampling tubes were injected into a gas chromatograph with Porapak Q column and hydrogen flame detector. Daily calibration curves were made on the gas chromatograph. Analyses were reproducible to $\pm 1\%$.

V EXPERIMENTAL PROCEDURE

For all experimental mixing rate runs, single phase air, single phase water, and two-phase air-water mixtures, the tracers were injected alternately in each channel. If equal values of the mixing rate were measured for injection in each subchannel then crossflow effects were assumed to be absent. Both channels were pressure balanced employing, if necessary, a clamp on the flexible hose connection at each subchannel exit to alter the hydraulic resistance. For some of the higher mass fluxes a drag screw located just after the injection probes was also used. The channels were balanced to $\pm 6/100$ inches water for single phase air runs and $\pm 1/10$ of an inch of water for the two-phase air-water runs. In the single phase water runs the total head was measured at each piezometric ring in both subchannels. There was no measurable radial pressure gradient.

The flow split was checked by leaving the methane tracer flowmeter at a given reading and injecting into each subchannel. The concentrations measured had a maximum deviation of 3%. Since equal amounts of tracer were injected in each subchannel, tracer concentrations are proportional to the total flow. Therefore subchannel flow rates were always within 3% of each other.

The range of experimental parameters employed here is shown in Tables 5.1, 5.2, and 5.3.

TABLE 5.1

Single Phase Air Parameter Range

An important part of the experiment was the method of tracer injection. As a result it was decided to use four and six hole injection probes to insure a uniform tracer distribution. The injection method was checked by using a dye tracer. For single phase water runs the tracer distribution appeared homogeneous within 2 inches of the injection point. For two phase runs the tracer distribution appeared homogeneous within 4 inches of the injection point. The use of the small holes in the probes caused the liquid to emerge as an expanding jet which extended to the walls of the subchannel. This insured that for two-phase runs the tracer was present both on the walls and in the core of the channel.

In order to assess the amount of methane tracer which would be dissolved in the water a calculation was employed using the non-injection subchannel, since a significant degree of solubility would greatly affect the data. (See Appendix V). For the maximum water flow rate the amount of methane dissolved was of the order of 0.005%.

VI RESULTS AND DISCUSSIONS

Turbulent mixing rates between two adjacent rectangular subchannels are reported for single phase air, single phase water, and two-phase air-water mixtures.

A. Single Phase Data

One approach in the correlation of turbulent mixing rates comes from that originally proposed for single channel experiments. Here a dimensionless variable ψ (the inverse of the Peclet number) is used to obtain a correlation in terms of a diffusivity. In this approach a distance term must be employed (as in the proposed equations 2.7, 2.8 and 2.9) in order to predict turbulent mixing rates.

A second approach in the correlation of mixing rate data involves the use of an equivalent Stanton number, N_{st} . For heat transfer the Stanton number is defined as:

$$N_{st} = \frac{h}{C_p G} = \frac{N_{Nu}}{N_{Re} N_{Pr}} = \frac{\text{heat actually transferred}}{\text{total heat capacity of fluid}}$$

For mass transfer an equivalent Stanton number can be defined as:

$$N_{st} = \frac{\phi h'}{G} = \frac{N_{Sh}}{N_{Re} N_{Sc}} = \frac{\text{mass actually transferred}}{\text{total mass flux}}$$

where

$$N_{Nu} = \frac{hDe}{k} = \frac{\text{total heat transfer}}{\text{conduction heat transfer}} = \text{Nusselt number}$$

$$N_{Re} = \frac{DeG}{u} = \frac{\text{inertial force}}{\text{viscous force}} = \text{Reynold's number}$$

$$N_{Pr} = \frac{C_p u}{k} = \frac{\text{momentum diffusivity}}{\text{thermal diffusivity}} = \text{Prandtl number}$$

$$N_{Sh} = \frac{h'D_e}{D} = \frac{\text{mass diffusivity}}{\text{molecular diffusivity}} = \text{Sherwood number}$$

$$N_{Sc} = \frac{u}{\rho D_e} = \frac{\text{momentum diffusivity}}{\text{molecular diffusivity}} = \text{Schmidt number}$$

The use of the mass transfer coefficient h' is analogous to the heat transfer coefficient h as shown below.

$$Q = h \Delta T \quad \text{heat transfer}$$

$$G^t = h' \Delta C \quad \text{mass transfer}$$

where

$$Q = \text{heat flux} \quad \text{BTU/hr ft}^2$$

$$h = \text{heat transfer coefficient} \quad \text{BTU/hr ft}^2 \text{ } ^\circ\text{F}$$

$$T = \text{temperature} \quad ^\circ\text{F}$$

$$G^t = \text{turbulent mass flux} \quad \text{lb/hr ft}^2$$

$$h' = \text{mass transfer coefficient} \quad \text{ft/hr}$$

$$C = \text{concentration} \quad \text{lb/ft}^3$$

The equivalent Stanton number can readily be obtained without defining an effective subchannel separation distance. In order to predict turbulent mixing rates in rod bundle geometries, data are necessary on all types of interacting subchannels for various gap widths and rod diameters.

Single phase water turbulent mixing data obtained here are tabulated in Table 1, Appendix I. Single phase air turbulent mixing data are recorded in Table 2, Appendix I.

Since there was a difficulty in defining a proper distance term in the first correlation method, the equivalent Stanton number approach is employed here. All the single phase mixing data are plotted

as a function of $\log N_{st}$ versus $\log N_{Re}$ in Fig. 6.1. An appreciable entrance effect is apparent. In Fig. 6.2 the single phase air data were crossplotted as N_{st} versus the number of equivalent diameters of interconnection length, (L/D) . The air turbulent mixing data and water turbulent mixing data overlap to form a continuous curve. This was expected since the Schmidt numbers for air and water are approximately equal. An exponential decrease in N_{st} was found for increasing L/D in Fig. 6.2. This effect is believed to be due to two factors. The first is the high initial mass transfer rate as the concentration profile is being developed. This is analogous to entrance effects in heat transfer, for example when the heat transfer coefficient is very high in the case of a cold fluid entering a channel with a high uniform temperature. The second factor is the increased turbulence when the two fluid streams meet at the upstream edge of the interconnection length.

In order to remove entrance effects in this analysis the average mixing rate for the last ten inches of the fourteen inch interconnection length was determined as follows. Mixing rate values for the four inch length were subtracted from those of the fourteen inch length. Then this value was used to calculate an average N_{st} over a length starting 4 inches downstream of the upstream edge of the interconnection length. The results are shown in Fig. 6.3 where N_{st} is found to vary as $N_{Re}^{-.13}$. This value is in agreement with the expected range for the exponent according to the mass-momentum transfer analogy [1]. This analogy predicts that the N_{st} should be proportional to the square root of friction factor. For turbulent flow $\sqrt{f} \propto (N_{Re})^{-.1}$.

FIG. 6.1
Single Phase Mixing Data N_{st} versus N_{Re}

FIG. 6.2 Single Phase Air Entrance Effects

FIG. 6.3

Comparison of Single Phase Data N_{St} versus N_{Re}

The data for the ten inch interconnection length were slightly low. It was found that the O-ring seal around the dividing strip was too tight at the centre of the interconnection length which could have caused bowing. Hence a modified Stanton number was not calculated for the ten inch interconnection length.

For the four inch interconnection length, the air mixing rates were determined for gaps of 40 and 100 mils. The mixing rates were found to be proportional to the gap width. The data are plotted in Fig. 6.4. These results however do not conclusively indicate that mixing rate is directly proportional to the gap width as they may have been influenced by entrance effects.

All data considered here are for square-square subchannel arrays. The available data are plotted in Fig. 6.3. Singletons data has been reanalyzed (See Appendix III) for purpose of comparison. Also the available square-square array subchannel data have been compared with the correlation predictions of St. Pierre [11], Bowring [13], Rogers [12] and Rowe and Angle [24] in Fig. 6.5. The results are tabulated in Appendix II. Rogers noted that his original correlation [25], based on multi-rod bundle experiments, predicted significantly higher mixing rates than the correlation based on subchannel data. However these higher mixing rates in rod bundle geometries could be due to spacers and end plates which are absent in the two channel experiments. The results of Rogers modified correlation were plotted in Fig. 6.5. This is a tentative correlation as Rogers presently is reanalyzing available mixing data. Values of Rogers original correlation [12] and

FIG. 6.4

Effect of Gap Width on 4 inch Interconnection
Length

TWO CHANNEL TURBULENT MIXING DATA FOR SQUARE - SQUARE ARRAYS

FIG. 6.5

Comparison of Mixing Data with Correlation

Moyers correlation [26] are given in Appendix II but are not plotted as the former were too high and the latter too low.

It is apparent from Fig. 6.5 that no one correlation adequately predicts mixing rates for all geometries. More data are required to account for the effects of gap width, gap shape, rod diameter, subchannel array and centroidal distance.

All the single-phase data averaged for the last ten inches of the fourteen inch interconnection length can be correlated as $N_{st} = .027 N_{Re}^{-.13}$ over the N_{Re} range $1 \times 10^4 - 1.5 \times 10^5$.

B. Two Phase Data

Two-phase air-water turbulent mixing was studied using an interconnection length ten inches long and 100 mils wide. Because of the entrance effects in this study the results are best considered relative to the single phase mixing rates with the same interconnection length and gap. The data are tabulated in Table 3, Appendix I.

Mixing rates were determined simultaneously for both the air and the water using separate tracers. The gas mixing rate ω_{gt}^t remained approximately constant when the mass flux was fixed and the quality varied from 20 to 100% (See Fig. 6.6). The air mixing rates under two phase flow conditions were less than those for single phase flow at the same total mass flux.

Significantly higher water mixing rates, ω_{lt}^t , were measured at the lower qualities. As the quality was increased for a fixed mass flux, the mixing rate dropped exponentially as shown in Fig. 6.6. Since laminar flow conditions would have existed for the single phase water

FIG. 6.6

Two-Phase Air-Water Mixing Rates

mixing rates at the same mass flux as the two-phase runs, they were not compared. However, the water mixing rates relative to the total water flow for a quality of 20% were appreciably higher than any single phase water mixing rates.

In Fig. 6.7 are shown the percentages of the air and water in the subchannel which mixed. At a fixed mass flux of 1.2×10^6 (lbm)/(hr)(ft)², the percentage of water which mixed decreased rapidly from approximately 10% at a quality of 20% to 4% at 80% quality. However, the percentage of air which mixed initially decreased from 8% at 20% quality to 2% at x=80% - then increased to 3% for single phase air flow or 100% quality. This behaviour was observed at all the mass fluxes studied. The increase in percentage air mixing from 80% quality to 100% quality is most likely due to the absence of the water film on the inter-connection length, which effectively decreased the area for air mixing.

It is postulated that these high values of mixing rates at the low qualities are the result of the transition from slug to annular flow. As was indicated in Fig. 3.3 the data points at a quality of 20% are just above the transitional curve on the flow regime map. The lowest mass flux at a quality of 20% was not taken as the flow was visually observed to be unstable. The air velocity was not sufficient to maintain annular flow and the wavy film on the wall periodically broke down to bridge the core. Some liquid downflow was also observed.

Investigations have been made of the air-water interface in a horizontal rectangular duct by Bemberis [31]. He allowed air to flow over a liquid surface under co-current flow conditions. As the air

FIG. 6.7

Air and Water Percentage Mixing
Rates

velocity over the liquid surface increased for fixed water flowrates, the following observations were made of the liquid-gas interface:

- (i) smooth flow
- (ii) ripples appeared
- (iii) the liquid surface was criss-crossed by ripple like waves oblique to the duct wall.
- (iv) large waves (roll waves) travelled over the liquid surface at a rate several times that of the average liquid velocity.
- (v) liquid was entrained into the air.

The most important observation of Bemberis is that of the formation of roll waves which have been observed often in two-phase flow. As the gas velocity increased, the roll waves grew smaller but more frequent. Entrainment takes place when the gas strips off the top of the waves. The size of the droplets entrained increased with increasing gas velocity.

In this investigation at a quality of 20% waves were observed along the channel walls much like the roll waves described by Bemberis. The effect of interaction between large amplitude roll waves from each subchannel could explain the high water mixing rates. These waves would also affect mixing in rod bundles. The data of Rowe and Angle for two phase mixing [24] between square-square subchannels show a peak in mixing at low qualities. The flow regime maps of Bergles and Suo [32] were used to determine the transition from slug to annular flow. The peak in mixing occurred at the transition. Also, in Rowe and Angles' boiling mixing experiments for a triangular-square array, there was no increase in mixing for two phase runs compared to single phase runs for a gap width of 20 mils.

It is possible that the effect of the roll waves (which have peak heights measured to be as high as 80 mils [33]) could have been minimized by the small gap width since the interconnection length at the gap was filled with liquid. In the larger gap width of 84 mils, mixing increased due to the interaction of the roll waves from each channel.

C. Two-Phase Pressure Drop Data

The two-phase pressure drop data were compared with the Lockhart-Martinelli correlation [34]. This correlation is based on an empirical analysis of pressure drop data and is subdivided into four sections, according to the Reynold's number of each phase flowing alone in the channel. The correlation gives the transition to turbulent flow at $N_{Re} = 2000$ and the transition to laminar flow at $N_{Re} = 1000$. The region $1000 < N_{Re} < 2000$ is defined as the transition region. In the pressure drop calculations it was found that the correlation was much better if the transition was defined at $N_{Re} = 1000$.

The comparison of the experimental data with the correlation is given in Appendix IV. The greatest deviation is at a quality of 80%. This is expected as the correlation was developed for annular flow.

VII. CONCLUSIONS

Experimental measurements have been made of turbulent mixing rates for single phase air, single phase water, and two-phase air-water mixtures. The turbulent mixing data exhibited entrance effects similar to those previously observed in heat transfer under analogous conditions. The single phase mixing data were correlated as $N_{st} = 0.027 N_{Re}^{-.13}$. The slope of $-.13$ in the correlation closely agreed with that which would be predicted employing the mass-momentum analogy. The experimental mixing rate data when compared with existing correlations, were all found to be inadequate for predicting mixing rates for the various subchannel arrays.

Two-phase mixing rates (expressed as a percentage of sub-channel flow) increased with decreasing quality and decreasing mass flux. It is postulated that the increased mixing is related to the slug-annular transition and the effect of high amplitude roll waves. The percentage of water mixing was always greater than that for air.

Additional turbulent mixing data are required for both single and two-phase flow conditions in order to determine mixing rates for all types of subchannel arrays.

NOMENCLATURE

Dimensions are given in terms of mass(M), length(L), time(t) and temperature(T).

| | | |
|----------|--------------------------------|-------------------|
| A | channel area | L |
| b | gap width | L |
| C | concentration of tracer | M/L^3 |

APPENDIX I

SINGLE PHASE MIXING DATA

APPENDIX I

Single Phase Mixing Data

The run numbers recorded in the following tables were coded as below. For example in Run 22R0 we have:

| Interconnection Length | Interconnection Width | Subchannel Injection | Quality |
|------------------------|-----------------------|----------------------|---------|
| 2 | 2 | R | 0 |

| Number Code | Interconnection length (inches) |
|-------------|---------------------------------|
| 1 | 2 |
| 2 | 4 |
| 3 | 6 |
| 4 | 10 |
| 5 | 14 |

| Number Code | Interconnection width (mils) |
|-------------|------------------------------|
| 1 | 40 |
| 2 | 100 |

| Letter Code | Subchannel Injection |
|-------------|----------------------|
| L | left |
| R | right |

| Number Code | = Quality % |
|-------------|-------------|
| 0 | 0 |
| 1 | 100 |
| 2 | 20 |
| 4 | 40 |
| 6 | 60 |
| 8 | 80 |

Methane concentrations are given in moles of methane per mole of mixture. Potassium concentrations are given as lb of potassium per lb of water.

TABLE II
SINGLE PHASE WATER MIXING DATA

APPENDIX II

COMPARISON OF MIXING RATES AND EXPERIMENTAL DATA USING PROPOSED CORRELATIONS

APPENDIX II

Comparison of Mixing Rates and Experimental Data Using Proposed Correlations

The correlations given in the literature survey, Chapter II, Section E, are compared to available subchannel mixing data. The results are given in tabular form in Tables II-1 and II-2.

TABLE I

COMPARISON OF PREDICTED MIXING RATES AND EXPERIMENTAL DATA

| MEASURED MIXING lb/hr.ft | PREDICTED MIXING USING CORRELATIONS lb/hr.ft | | | | | | | | (b/d) |

APPENDIX III

ANALYSIS OF SINGLETON'S DATA

APPENDIX III

Analysis of Singleton's Data

Singleton [22] analyzed his data in terms of a dimensionless mixing coefficient which could be related to $1/N_{Pe}$ by assuming values for gap width and subchannel separation distance. His concentration data were used to evaluate an equivalent Stanton number. The procedure is outlined below.

Subchannel Flow Designations

$$w_{l1} + w_{cl1} = w_L = w_{l2} + w_{cl2} \quad (A.1)$$

$$w_{r1} + w_{cr1} = w_R = w_{r2} + w_{cr2} \quad (A.2)$$

$$w_{cl1} = w_{l1} \frac{V_c}{V_1} = \frac{A_c}{A_1} \quad (A.3)$$

Denote $\frac{V_c}{V_l} \frac{A_c}{A_l} = \frac{V_c}{V_r} \frac{A_c}{A_r}$ by K

i.e. The velocity in the centre channel is greater than in the outer channels.

The inlet concentration in channel one can be written as

$$\begin{aligned} LC1 &= \frac{C_{l1} w_{l1} + C_{lc1} w_{lc1}}{w_L} = \frac{C_{l1} w_{l1} + K C_{lc1} w_{lc1}}{w_{l1} (1+K)} \\ &= \frac{C_{l1} + K C_{lc1}}{1+K} \end{aligned} \quad (A.5)$$

FIG. III-2

Concentration Profile

The concentration gradient can be approximated as linear.

Therefore:

$$C_{lc1} = .75 C_{c1}$$

Now the concentration in the left channel at the entrance can be written as:

$$LC1 = \frac{C_{l1} + K C_{c1} (.75)}{1+K} \quad (A.6)$$

Similarly,

$$RC1 = \frac{C_{r1} + K C_{c1}}{1+K} \quad (A.7)$$

$$LC2 = \frac{C_{l2} + K C_{c2} (.75)}{1+K} \quad (A.8)$$

$$RC2 = \frac{C_{r2} + K C_{c2} (.25)}{1+K} \quad (A.9)$$

The mixing rate can now be determined from a mass balance.

$$w_{L1} = w_{L2} = w_{R1} = w_{R2} = w \quad (A.10)$$

$$w (LC1) + w^t (RC1 + RC2) - w \frac{t(LC1 + LC2)}{2} = w (LC2) \quad (A.11)$$

$$\frac{w^t}{w} = \frac{2(LC1-LC2)}{(LC1+LC2-RC1-RC2)} \quad (A.12)$$

$$N_{st} = \frac{G^t}{G} = \frac{w^t/A^t}{w/A} = \frac{2(LC1-LC2)}{(LC1+LC2-RC1-RC2)} (A^t/A_L) \quad (A.13)$$

From a tracer balance

$$LC1+RC1 = LC2+RC2 \quad (A.14)$$

$$LC1-LC2 = RC2-RC1 \quad (A.15)$$

$$N_{st} = \frac{2(RC2-RC1)}{(LC1+LC2-RC1-RC2)} (A^t/A_L) \quad (A.16)$$

Using Singletons concentration data a Stanton Number was calculated using Eq. (16). The calculated values are shown in Table III-1.

TABLE III-I

ANALYSIS OF SINGLETON'S DATA

| SQUARE FILTERS | | | | ROUND FILTERS | | | |
|-------------------|--------------------|------------------------------------|------|-------------------|--------------------|------------------------------------|------|

APPENDIX V

CALCULATION OF SOLUBILITY OF METHANE IN WATER

APPENDIX V

Calculation of Solubility of Methane in Water

The example used for the following calculation will consider the highest mass flow and lowest quality since this represents the case for the maximum error due to the solubility of methane.

$$\text{Pressure} = 50 \text{ psia}$$

$$T = 25^{\circ}\text{C}$$

$$\text{Air flow} = 120 \text{ lb/hr}$$

$$\text{Water flow} = 480 \text{ lb/hr}$$

$$\text{Methane concentration} = .0033 \text{ by volume}$$

$$H \text{ (Henry Low Constant [35])} = 4.13 \times 10^4 \frac{\text{atm.}}{\text{mole fraction of solute in solution}}$$

$$P_m = \text{partial pressure methane}$$

$$= .0033 \times \frac{50}{14.7} = .0112 \text{ atm.}$$

$$X_m = \text{mole fraction methane in solution}$$

$$= \frac{.0112}{4.13 \times 10^4} = 2.71 \times 10^{-7}$$

$$\text{Number of moles of water} = \frac{480}{18} = 26.7 \text{ moles/hr}$$

$$\begin{aligned} \text{Number of moles of methane dissolved} &= 2.71 \times 10^{-7} \times 26.7 \\ &= 7.25 \times 10^{-6} \text{ moles/hr} \end{aligned}$$

$$\begin{aligned} \text{Number of moles of methane available} &= .0033 \times \frac{120}{29} \\ &= .0137 \text{ moles/hr} \end{aligned}$$

$$\begin{aligned} \text{Percent dissolved} &= \frac{7.25 \times 10^{-6}}{1.37 \times 10^{-2}} (100) \\ &= .0053\% \end{aligned}$$

VITA AUCTORIS

- 1943 Born in Sault Ste. Marie, Ontario
- 1962 Graduated from St. Mary's High School in Sault Ste. Marie
- 1966 Graduated from University of Windsor with degree of B.A.Sc. in Chemical Engineering
- 1966 Accepted into the Graduate School of University of Windsor as a candidate for the degree of M.A.Sc. in Chemical Engineering
